NOAA Technical Memorandum NMFS

The National Oceanic and Atmospheric Administration (NOAA), organized in 1970, has evolved into an agency which establishes national policies and manages and conserves our oceanic, coastal, and atmospheric resources. An organizational element within NOAA, the Office of Fisheries is responsible for fisheries policy and the direction of the National Marine Fisheries Service (NMFS).

In addition to its formal publications, the NMFS uses the NOAA Technical Memorandum series to issue informal scientific and technical publications when complete formal review and editorial processing are not appropriate or feasible. Documents within this series, however, reflect sound professional work and may be referenced in the formal scientific and technical literature.

NOAA Technical Memorandum NMFS

This TM series is used for documentation and timely communication of preliminary results, interim reports, or special purpose information. The TMs have not received complete formal review, editorial control, or detailed editing.

Introduction

Distinct populations of planktonic and micronektonic marine organisms appear to be maintained around islands. These include populations of meso-pelagic fishes (Reid, et al. 1991), larval fishes (Leis and Miller, 1976; Leis, 1982; Boehlert, et al. 1992), and zooplankton (Leis, 1982). The relative importance of physical and biological processes in the maintainence of these populations is unclear. Detailed vertical distribution data for zooplankton around islands is lacking, so that the degree to which vertical distribution can affect the ability of zooplankton to be retained around islands cannot be assessed. To address this problem we have determined the vertical distribution of four species of copepods together with the physical structure of the water column for four seasonal transects off the leeward and windward coasts of the island of Oahu in the Hawaiian Archipelago. This data report is intended to provide a detailed data summary of station information and copepod abundances that will be used for future publication of the analyzed data set. A data report on larval fish distributions from the same seasonal cruises will also be issued (Boehlert and Mundy, in prep), and the distribution of tuna larvae has been discussed (Boehlert and Mundy, 1994).

For our analysis of copepod distributions we chose two neritic/nearshore species, the calanoid *Undinula vulgaris* (Dana) and the pontellid *Labidocera madurae* (Scott), and two oceanic species, both calanoids, *Cosmocalanus darwinii* (Lubbock) and *Scolecithrix danae* (Lubbock). *U. vulgaris* and *C. darwinii* are closely related, the latter species formerly having been classified in the genus *Undinula* . *C. darwinii* and *S. danae* are widespread species, but are strictly oceanic (Grice, 1961). *U. vulgaris* is also a widespread species found throughout warm, tropical waters (e.g., Wilson, 1950; Michel and Foyo, 1976), but it most commonly occurs in neritic waters, where it can be very abundant (Grice, 1961). *L. madurae* is little reported in the literature and appears to be associated with islands in the tropical Indo-Pacific (Scott, 1909). Leis (1982) found *U. vulgaris* to be most abundant at 0.5–1 km from shore off Kahe Point on the leeward Oahu coast, and *L. madurae* at 0.2 km. All four species are of similar sizes, ranging from 2.0-2.6 mm for females and 1.6-2.0 mm for males.

Methods

Day/night vertical series of plankton samples were collected during onshore/offshore transects on 6-15 September and 12-20 December, 1985, and 8-18 April and 24 June - 2 July, 1986. Stations were occupied at 1.8, 9.3, and 28 km off Kahe Point on the leeward Oahu coast (identified as L1, L5, and L15) and 3.7, 9.3, and 28 km off Kaneohe Bay on the windward side (W2, W5, W15) (see Figure 1 in Boehlert and Mundy, 1994). Tows were taken as nearly parallel to the coast as weather conditions would allow. The nearshore stations were occupied near the 100m depth contours, but, due to weather constraints and the steep bathymetry, some tows ended over deeper water. Sampling was done with a 1 m^2 MOCNESS multiple opening/closing net and environmental sensing system (Weibe et al. 1985), which provided measurements of depth, conductivity, temperature, and several characteristics of net performance (velocity, mouth angle, water volume filtered). MOCNESS samples were collected between 0-80 m at the nearshore stations (10 m intervals from 0-60m plus 60-80 m) and between 0-200 m at the offshore stations (20 m intervals from 0-120 m and 40 m intervals from 120-200m). Surface neuston samples were taken with a 0.49 m^2 modified Manta net, which sampled the 0-0.7 m (neuston) depth interval. Replicate night and day tows were taken at each site (identified as N1, N2 and D1, D2). Tows at several depth intervals within the thermocline were taken at some stations, and data from one such tow (TC8602 L5 thermocline) are reported here. A mechanical flowmeter attached to the MOCNESS frame above the nets provided filtration volume estimates (Wiebe et al. 1985) and densities of copepods were calculated as number of individuals per 1000 cubic meters. Water column abundance was calculated by multiplying density x 1000 x the depth range sampled within each stratum and summing the resultant values for all strata in a tow. Water column abundance is thus presented as total number of individuals/ m^2 sea surface area. For depth intervals where the measured end and start depths of successive strata were not identical, the midpoint between the end and start depths was used in calculations. Station and environmental data are presented in Table 1.

Identifications of adult females and males of *Undinula vulgaris* and *Cosmocalanus* (formerly *Undinula*) *darwinii* were from descriptions by Mori (1937), *Scolecithrix danae* from Rose (1933), and *Labidocera madurae* from the original description by Scott (1909). According to Leis (1978) the species identification of the *Labidocera* in nearshore Hawaiian waters is uncertain, but most closely resembles the description of Scott (1909) for *L. madurae.*

Preserved samples from cruises TC8504 and TC8602 were subsampled using a Folsom splitter. Later subsampling, for *Undinula vulgaris* alone, was done with a 10 ml Stempel pipet, drawing fractions from a known sample volume. Due to occasional large differences in abundance among species, different sized fractions were sometimes counted for the different species. For the first 18 samples, replicate subsamples of the Folsom splitter were counted to check for the accuracy of subsampling. After the first 6 samples had been counted, the splitting was modified by manually stirring the sample in the splitter with a plastic paddle as the split was being made. This modification increased the accuracy of the split from 83% (n=6) to 91% (n=12), where percent = the lower count of the two subsamples divided by the higher count x 100 (minimum of 100 individuals in each subsample). This was particularly necessary for *Scolecithrix danae*, which tended to be unevenly distributed in the sample due to the combination of a relatively high density compared to the other copepods and a tendency to collect air bubbles on its carapace. Successive splits did not introduce appreciable error into the counts, as the lower count of replicate splits averaged 90-94% of the larger over a range of 5 successive splits (n=12).

The samples that were counted from the four cruises are indicated in Table 1. Copepods from the nearshore stations (L1, W2) were counted over the entire depth range sampled (0-80m), while the offshore stations (L5, L15, W5, W15) were counted from the surface to depth until the target copepods were rare or absent (usually to 120 or 160 m maximum depth). For the September 1985 cruise, TC 8504, the four copepod species were counted in all vertical series except W2N2. In the latter series, *Undinula vulgaris* was so overwhelmingly dominant that counting for other species was impractical. For the other three cruises, selected samples and species were counted. Only for one replicate series, of the April 1986 leeward transect, were all four species counted. In the other transects, *U. vulgaris* was the only species counted from the MOCNESS series, with *Labidocera madurae* being counted from Manta Net samples of all transects. This strategy provided a complete vertical and horizontal distribution for all species during the leeward and windward September transects and the leeward April transect, as well as seasonal profiles for *U. vulgaris* and *L. madurae* during the other transects.

Results

Total water column abundances (Table 2) confirm the neritic/nearshore distribution of both *Undinula vulgaris* and *Labidocera madurae*, as the abundance of both species drops rapidly moving away from shore. Abundances of the oceanic species *Cosmocalanus*

darwinii and *Scolecithrix danae* show a corresponding decrease in abundance moving onshore. The relative decrease in abundance of the oceanic species in nearshore waters is far less than that of their nearshore counterparts in oceanic waters. Water column abundances of *U. vulgaris* and *L. madurae* decrease by 1-3 orders of magnitude moving offshore, while abundances of *C. darwinii* and *S. danae* decrease by a factor of only 2-5 moving onshore. However, it should be noted that comparing absolute abundances between windward and leeward sides, and between seasons, is complicated by the possibility that physical processes may be shifting the center or edges of a species' distribution nearer or further from the island.

The estimates of total water column abundance of *Undinula vulgaris*, *Cosmocalanus darwinii*, and *Scolecithrix danae* (Table 2) at the nearshore leeward and windward stations (L1, W2) are minimum estimates because the entire vertical range of these species was not sampled there. Virtually all of the vertical range of these three species was covered by our sampling in offshore waters (Table 3), but these species sometimes were abundant at depths of 80-100m, which exceeds the maximum sampling depth at the L1 and W2 stations (maximum sampling depth of 80 m over a nominal bottom depth of 100 m). In the nearshore stations the densities of *U. vulgaris*, *C. darwinii*, and *S. danae* frequently were high in the deepest 60-80m stratum. Thus, while peak densities were generally in shallower stratum, a potentially significant fraction of the population sometimes may have been present below our sampling range at the nearshore stations. This problem does not apply to *Labidocera madurae*, because of its shallow vertical distribution.

Vertical distributions of the four copepod species in numbers per 1000 cubic meters, broken down into male, female, and total adult, are given in Tables 3-6. *Undinula vulgaris* was the most abundant species in nearshore samples, both windward and leeward of Oahu, occurring in densities of up to 800 adults/cubic meter (Table 3: TC8504 W2N2, 45-50 m depth stratum). During TC8504 (September) *Labidocera madurae* was largely limited to the upper 1 m of the water column, except for one series that had higher abundances in the 1-10m sample (L1N2). During the leeward transect of TC8602 (April), *L. madurae* was distributed throughout the water column at the 1.8 and 9.3 km stations, but only in the surface layer at the 28 km station. *Scolecithrix danae* demonstrated the most pronounced and consistent day/night differences in vertical distribution, with a depth range of approximately 60-100 m during the day and 0-40 m at night. A variable degree of apparent migratory behavior was exhibited by *U. vulgaris* and *Cosmocalanus darwinii*. Variable patterns are evident here over relatively short distances. For instance, during TC8504 (September) all three species had pronounced differences in day and night distributions at the 27.8 km leeward station, but relatively little difference at the 9.3 km station.

Abundances of *Labidocera madurae* in Manta net samples are given in Table 7 and include additional stations not shown in Tables 3-6. *L. madurae* distributions show a trend toward higher abundances on the leeward side. It is likely that this is due to the leeward station being 1.8 km from shore vs. 3.7 km on the windward side, as *L. madurae*'s peak abundance in Leis (1982) was at 0.2 km from shore. *L. madurae* also tended to be more abundant at the offshore stations on the leeward side compared to windward, in particular being consistently very rare or absent at the windward 28 km stations. The April cruise showed an unusual pattern in *L. madurae* distribution, in that the copepod was distributed throughout the upper 100 m at the leeward 1.8 and 9.3 km stations, and was also uncharacteristically abundant at the 9.3 km station (Table 5). At other stations *L. madurae* was found only in surface waters. The windward transects in April also displayed unusual patterns in that the abundance of *Undinula vulgaris* was very low nearshore. Though the oceanic indicator species were not counted in these samples, it was noted that they and other typically oceanic species (e.g., *Neocalanus gracilis*, *Haloptilus longicornis*) were present in the nearshore windward (W2) samples.

General features of the distribution of these copepod species around Oahu conform to earlier characterizations as insular or oceanic taxa. Detailed interpretation of the distributional patterns of copepods is beyond the scope of this data report. Analysis of the physical structure of the water column during sampling is not presented here. A detailed discussion of the effects of water column structure and other influences on the distribution of copepods near Oahu will be the subject of further analysis based on the data tabulated here.

Acknowledgments

We would like to thank Bruce Mundy for his assistance in coordinating the data gathering and Ron Yoshimoto for assistance in counting samples. We also thank the crew of the NOAA vessel Townsend Cromwell for their work during the cruises collecting these data. We thank Bruce Mundy and H. Geoffrey Moser for reviews of an earlier draft of this data report. This research was conducted while the senior author held a National Research Council Postdoctoral Research Associateship at the NMFS Honolulu Laboratory. Their support is gratefully acknowledged.

RECENT TECHNICAL MEMORANDUMS

Copies of this and other NOAA Technical Memorandums are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22167. Paper copies vary in price. Microfiche copies cost $9.00. Recent issues of NOAA Technical Memorandums from the NMFS Southwest Fisheries Science Center are listed below:

NOAA-TM-NMFS-SWFSC-205 An assessment of the 1994 status of harbor porpoise in California.
J. BARLOW and K. FORNEY
(June 1994)

206 The Hawaiian monk seal on Laysan Island, 1990.
K.B. LOMBARD, B.L. BECKER, M.P. CRAIG, G.C. SPENCER, and K. HAGUE-BECHARD
(June 1994)

207 The estimation of perpendicular sighting distance on SWFSC research vessel surveys for cetaceans: 1974 to 1991.
J. BARLOW and T. LEE
(August 1994)

208 The physical oceanography off the central California coast during February-March and May-June 1992: a summary of CTD data from pelagic young-of-the-year rockfish surveys.
K.M. SAKUMA, H.A. PARKER, S. RALSTON, F.B. SCHWING, D.M. HUSBY, and E.M. ARMSTRONG
(September 1994)

209 The physical oceanography off the central California coast during March and May-June, 1993: a summary of CTD data from pelagic young-of-the-year rockfish surveys.
